A LARGE DEVIATIONS APPROACH TO SENSOR SCHEDULING FOR DETECTION OF CORRELATED RANDOM FIELDS

Youngchul Sung, Lang Tong, and H. Vincent Poor

ABSTRACT

The problem of scheduling sensor transmissions for the detection of correlated random fields using spatially deployed sensors is considered. Using the large deviations principle, a closed-form expression for the error exponent of the miss probability is given as a function of the sensor spacing and signal-to-noise ratio (SNR). It is shown that the error exponent has a distinct characteristic: at high SNR, the error exponent is monotonically increasing with respect to sensor spacing, while at low SNR there is an optimal spacing for scheduled sensors.

1. INTRODUCTION

One of the most critical design constraints for large scale sensor networks is energy efficiency. In the context of detecting spatially correlated signals, this means that, given a desired level of detector performance, one should minimize the amount of data required, and collect data from judiciously chosen areas.

We consider in this paper the detection of a one dimensional diffusion process that has a spatial state space structure as illustrated in Fig. 1. Specifically, we assume that the underlying signal $s(x)$ is the stationary solution[1] of the diffusion equation

$$\frac{ds(x)}{dx} = -As(x) + Bu(x), \quad x \geq 0, \tag{1}$$

where $A \geq 0$ and B are known, and the initial condition is given by $s(0) \sim \mathcal{N}(0, \Pi_0)$. The input process $u(x)$ is zero-mean white Gaussian, independent of both sensor noise and $s(0)$.

Poor was supported in part by the Office of Naval Research Grant N00014-03-1-0102.

[1]The stationary solution of (1) requires a condition on A, B, Π_0 given by $\Pi_0 = \frac{B^2}{2A}$.

We assume that each sensor in the field takes a noisy measurement. At location x_i, the sensor measurement y_i comes from the following binary hypotheses

$$\begin{array}{lll} H_0 & : & y_i = w_i, \\ H_1 & : & y_i = s_i + w_i, \quad i = 1, 2, \cdots, n, \end{array} \tag{2}$$

where $s_i \stackrel{\Delta}{=} s(x_i)$, and w_i are i.i.d. sensor measurement noises from $\mathcal{N}(0, \sigma^2)$ with a known variance σ^2. We will not focus here on minimizing the number of bits for the quantization of y_i, nor will we tackle the problem of how y_i are sent to the fusion center for detection. These are important design issues that must be treated separately. Our focus in this paper is that, if data are to be collected from the sensor field, where they should be collected. For energy efficiency, we aim to find a scheduling scheme that require as few samples as possible.

1.1. Summary of Results

We adopt the Neyman-Pearson formulation by fixing the detector size α and minimizing the miss probability when the number n of samples is large. Specifically, we are interested in two closely connected design problems: the locations $\mathcal{X} = \{x_i\}$ where data should be collected, and the rate of decay of miss probability for detectors of size α. We will make the assumption that samples are collected uniformly with equal spacing $\Delta_i = \Delta$. Such an idealized assumption can only be approximated in practice, but it does provide an analytically tractable formulation that leads to insights into energy efficient data collection.

The miss probability $P_M(\Delta, n; \alpha, \text{SNR})$ is a function of sensor spacing Δ, the sample size n as well as detector size α and SNR $\Gamma \stackrel{\Delta}{=} \frac{\Pi_0}{\sigma^2}$. The energy efficient scheduling problem can then be formulated as one of optimizing the error exponent $K_\alpha(\Delta, \text{SNR})$ under the large deviation principle where

$$K_\alpha(\Delta, \Gamma) = \lim_{n \to \infty} \frac{1}{n} \log P_M(\Delta, n; \alpha, \Gamma). \tag{3}$$

The connection of the above formulation with energy efficient sensor scheduling is natural when the sample size n is directly related with the number of transmissions (such as the case in Sensor Networks with Mobile Access (SENMA)).

We derive a closed-form expression for the error exponent $K_\alpha(\Delta, \Gamma)$ of miss probability (which is independent of α) by exploiting the state-space structure of alternative hypotheses and making a connection with Kalman filtering. We show next that $K_\alpha(\Delta, \Gamma)$ has a distinct phase transition: when SNR $\Gamma > 1$, $K_\alpha(\Delta, \Gamma)$ is a monotonically increasing function of Δ, indicating that sensor spacing Δ should be made as large as possible (for fixed but large sample size). When SNR $\Gamma < 1$, on the other hand, $K_\alpha(\Delta, \Gamma)$ achieves the maximum at some Δ^*, which means that there is an optimal spacing among collected samples. We also provide an

implicit equation for Δ^*. We also present simulation results to demonstrate the predicted behavior.

1.2. Related Work

The detection of Gauss-Markov process in Gaussian noise is a classical problem. See [5] and references therein. Our work relies on the connection between likelihood ratio and the innovation process through Kalman filtering by Schweppe [6]. While the connection between Kalman filter and error exponent is a contribution of this paper, there is an extensive literature on the large deviation approach to the detection Gauss-Markov process [9, 10, 11, 12, 13, 14, 15]. These results do not provide explicit expressions (with an exception for noiseless AR processes) from which optimal scheduling can be obtained.

The sensor scheduling problem can also be viewed as a sampling problem. To this end, Bahr and Bucklew [11] optimized the exponent numerically under a Bayesian formulation. For a specific signal model (low pass signal in colored noise), they showed that the optimal sampling depends on SNR, which we also show in this paper in a different setting.

2. SYSTEM MODEL

We derive the discrete model for the sampled data of the signal $s(x)$ similarly to [4]. For equally spaced sensors with spacing Δ, the dynamics of sampled signal are described by

$$\begin{aligned} s_{i+1} &= as_i + u_i, \\ a &= e^{-A\Delta}, \ u_i = \int_0^\Delta e^{-Ax} Bu(x_{i+1} - x)dx, \end{aligned} \tag{4}$$

The mean and variance of process u_i are given by

$$\mathbb{E}u_i = 0, \quad Q \triangleq \text{Var}(u_i) = \Pi_0(1 - a^2). \tag{5}$$

The signal samples $\{s_i\}$ form an autoregressive sequence under H_1. Notice that $\mathbb{E}s_i^2 = \Pi_0$ for all i and the value of a determines the amount of correlation between signal samples. For i.i.d. signal samples we have $a = 0$ and $a = 1$ for the perfectly correlated signal. Notice also that the noisy observation $\{y_i\}$ are not autoregressive; they follow the hidden Markov model.

3. ERROR EXPONENT

In this section, we investigate the performance of Neyman-Pearson detector with a level $\alpha \in (0, 1)$. We present a closed-form expression of the *error exponent* of miss probability $K_\alpha(\Delta, \Gamma)$ defined in (3). The theorem below comes from the fact that the limit of the normalized log-likelihood ratio under H_0 is the best error exponent for general ergodic cases[16]. By expressing the log-likelihood ratio through the innovation representation, we make the closed-form calculation of error exponent tractable.

Theorem 1 (Error exponent) *For the Neyman-Pearson detector of the hypotheses (2, 4) with level $\alpha \in (0, 1)$ (i.e. $P_F \leq \alpha$) and $0 \leq a \leq 1$, the best error exponent of miss probability is independent of α and is given by*

$$K_\alpha(\Delta, \Gamma) = -\frac{1}{2}\log\frac{\sigma^2}{R_e} + \frac{1}{2}\frac{\tilde{R}_e}{R_e} - \frac{1}{2}, \tag{6}$$

where R_e and $\tilde{R}_e$ are the steady-state variances of the innovation process of y_i calculated under H_1 and H_0, respectively. Specifically, R_e and $\tilde{R}_e$ are given by

$$R_e = P + \sigma^2, \tag{7}$$

$$\tilde{R}_e = \sigma^2\left(1 + \frac{a^2P^2}{P^2 + 2\sigma^2P + (1 - a^2)\sigma^4}\right), \tag{8}$$

$$P = \frac{\sqrt{[\sigma^2(1 - a^2) - Q]^2 + 4\sigma^2Q} - \sigma^2(1 - a^2) + Q}{2}, \tag{9}$$

In frequency domain,

$$K_\alpha(\Delta, \Gamma) = \frac{1}{2\pi}\int_0^{2\pi} D(\mathcal{N}(0, \sigma^2)||\mathcal{N}(0, S_y(\omega)))\, d\omega, \tag{10}$$

where $D(\cdot||\cdot)$ is the Kullback-Leibler distance, and the spectrum $S_y(\omega)$ of $\{y_i\}$ under H_1 is given by

$$S_y(\omega) = \sigma^2 + \frac{\Pi_0(1 - a^2)}{1 - 2a\cos\omega + a^2}. \tag{11}$$

Proof: see [17]. ■

For notational convenience, we use K for the error exponent.

3.1. Properties of Error Exponent

First, it is easily seen from Theorem 1 that K is a continuous function of the correlation coefficient a ($0 \leq a \leq 1$) for a given Π_0 and σ^2 since $R_e \geq \sigma^2 > 0$.

Theorem 2 *The error exponent is positive for any SNR Γ and $0 \leq a < 1$. Furthermore,*

- *(i) for i.i.d. observations ($a = 0$), the error exponent reduces to the Kullack-Leibler distance $D(p_0||p_1)$ where $p_0 \sim \mathcal{N}(0, \sigma^2)$ and $p_1 \sim \mathcal{N}(0, \Pi_0 + \sigma^2)$;*
- *(ii) for Perfectly correlated signal ($a = 1$), the error exponent is zero for any SNR Γ, and the miss probability is bounded by*

$$(\frac{1}{\sqrt{2\pi}} - D)cn^{-1/2} \leq P_M \leq \frac{1}{\sqrt{2\pi}}cn^{-1/2} \tag{12}$$

for sufficiently large n, where c and $D \in (0, \frac{1}{\sqrt{2\pi}})$ are positive constants.

The positivity of K is immediate from Theorem 1. The case when $a = 0$ corresponds to the *Stein's lemma* for the i.i.d. case. Unless $a = 1$, the miss detection probability always decays exponentially.

For the perfectly correlated case ($a = 1$), the miss probability does not decay exponentially; it decays with $\Theta(\frac{1}{\sqrt{n}})$ as shown in (12). This is explained by the form of the optimal detector. It can be shown that the sufficient statistic is given by

$$T = |\sum_{i=1}^n y_i|^2. \tag{13}$$

Under H_0, we have $\sum_{i=1}^n y_i \sim \mathcal{N}(0,\ n\sigma^2)$. Since $f(x) = x^2$ is symmetric about zero, the Neyman-Pearson detector with level α is simply given by

$$\delta_n^{cor} = \mathbf{1}_{\{|\sum_{i=1}^n y_i| \geq z_n\}}, \tag{14}$$

where $z_n = \sqrt{n}\sigma Q^{-1}(\frac{\alpha}{2})$. ($Q(\cdot)$ is the tail probability of standard normal distribution). Since $P_{1,n} = \mathcal{N}(0,\ n^2\Pi_0 + n\sigma^2)$, the probability of missing is given by

$$P_M = 1 - 2Q\left(\frac{\sqrt{n}\sigma Q^{-1}(\frac{\alpha}{2})}{\sqrt{n^2\Pi_0 + n\sigma^2}}\right). \tag{15}$$

For large n, P_M behaves as $1 - 2Q(\frac{c}{\sqrt{n}})$ where c is a constant, which leads to (12).

Having obtained the behavior of error exponent at two extreme correlation cases, we now show that the error exponent has distinct characteristics at different SNR regimes.

Theorem 3 (K vs. correlation - high SNR) *K is monotone decreasing as the correlation strength increases (i.e. $a \uparrow 1$) if the SNR $\Gamma > 1$.*

The above theorem shows that the i.i.d. observations give the best error performance for the same SNR with the maximum error exponent $D(\mathcal{N}(0,1)||\mathcal{N}(0,1+\Gamma))$ when SNR is larger than unity. Fig. 2 (left) shows the error exponent as a function of the correlation coefficient a. In the context sensor scheduling, if n transmissions are required for the desired miss probability, it is best to maximize the distances between the scheduled sensors. The intuition is that, at high SNR, the signal component in the observation is strong, and the innovation process contains more information about the hypotheses. Thus there is benefit to make the signal less correlated.

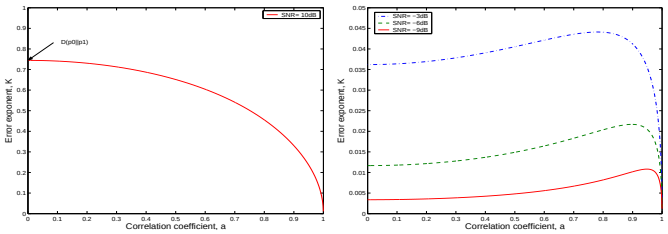

Fig. 2. K vs. a (left:SNR=10 dB, right:SNR=-3,-6,-9 dB)

In contrast, error exponent at low SNR is not monotonic, and there exists an optimal correlation. Fig. 2 (right) shows the error exponent for the case that the SNR is less than unity. As shown, the i.i.d. case is not the best for the error performance for the same SNR. The error exponent initially increases as a increases, and then decreases to zero as a approaches one. For SNR of -6 dB the error exponent is less than the case of -3 dB and it is seen that a_m is shifted closer to one. The following theorem characterizes the optimal correlation.

Theorem 4 (K vs. correlation - low SNR) *There exists a non-zero value a_m of the correlation coefficient that achieves the maximum K for SNR < 1, and a_m is given by solving the following equation.*

$$[1 + a^2 + \Gamma(1 - a^2)]^2 - 2(r_e + \frac{a^4}{r_e}) = 0, \tag{16}$$

where $r_e = R_e/\sigma^2$. Futhermore, a_m converges to one as SNR Γ goes to zero.

At low SNR, noise in the observation dominates. Thus making signal more correlated provides the benefit of noise averaging. The lower the SNR, the stronger the correlation is desired as shown in Fig. 2 (right). Note however that excessive correlation in the signal doesn't provide new information by the observation. Notice also that the maximum value of error exponent is much larger than the value for i.i.d. case at lower SNR. Hence, the optimal correlation gives much better performance with the same number of sensor observations for low SNR cases.

A significance of the above theorem is the determination of optimal sensor spacing. In particular, the optimal distance is given by

$$\Delta^* = -\log(a_m)/A, \tag{17}$$

for the same underlying physical phenomenon described by (1).

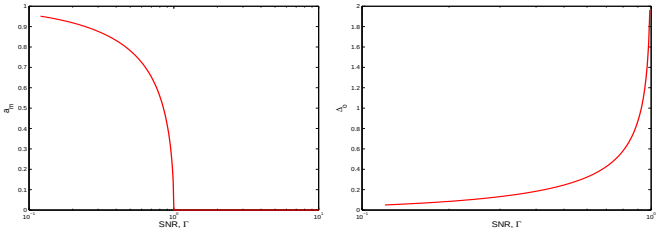

Fig. 3. Left: a_m vs Γ, right:Δ^* vs $\Gamma(< 1)$

Fig. 3 shows the value of a_m that maximizes the error exponent as a function of SNR. As shown in the figure the SNR of *unity* gives sharp transition between two different behaviors of error exponent w.r.t. correlation strength.

Finally, we investigate the behavior of the error exponent w.r.t. SNR.

Theorem 5 (K vs SNR) *The error exponent K is monotone increasing as SNR increases for a given correlation coefficient $0 \leq a < 1$. Moreover, at high SNR K increases linearly with* log *SNR.*

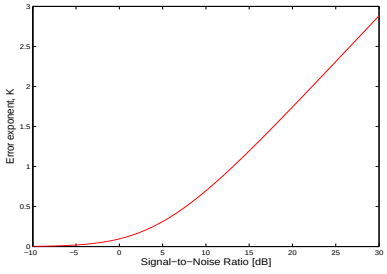

Fig. 4. K versus SNR ($a = e^{-1}$)

The log SNR increase of K w.r.t. SNR is similar to the case of diversity combining of Rayleigh-faded multipaths in additive noise since in both cases the signal component is random. Comparing with the detection of a deterministic signal in noise where the error exponent is proportional to SNR, the increase of error exponent w.r.t. SNR is much slower for the case of stochastic signal in noise.

3.2. Sensor Placement

So far we have assumed that sensors have been placed and the problem is to schedule the transmission of selected sensors. A

related problem is sensor placement. Should n sensors be placed to cover as large an area as possible, or should they be clustered in a subregion of the signal field? Theorem 3 suggests that, at high SNR, these sensors should be placed with maximum separation subject to the size of the field. At low SNR, however, sensors should be placed with the optimal separation. This implies that, if the sensor field is large, it is better to cluster the sensor in some region, leaving other areas without sensors.

4. SIMULATION RESULTS

We considered the Neyman-Pearson detector of first-order autoregressive signal described by (4). We considered SNR of 10 dB and - 3 dB, and several a for each SNR. The probability of false alarm was set 0.1% for all cases. Fig. 5 shows the miss probability w.r.t.

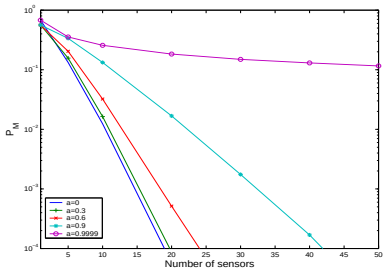

Fig. 5. P_M vs. # of sensors (SNR=10dB)

number of sensors for 10 dB SNR. It is shown that the i.i.d. case ($a = 0$) has the largest slope for error performance, and the slope of error decay is monotonically decreasing as a increases to one. Notice that the error performance for the same number of sensors is significantly different for different correlation strength even for the same SNR, and the performance for weak correlation is not much different from i.i.d. case predicted by Fig. 2 (left). (We can see that the slope decreases suddenly near $a = 1$.) It is shown that the miss probability for highly correlated case ($a = 0.9999$) is not exponenitally decay.

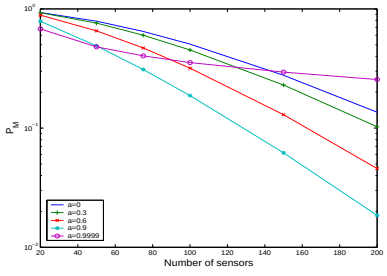

Fig. 6. P_M vs. # of sensors (SNR=-3dB)

The error performance for SNR of -3 dB is shown in Fig. 6. It is seen that the slope increases as a increases from zero, and reaches maximum with sudden decrease after the maximum. Notice that the error curve is still not a straight line for low SNR case due to the $o(n)$ term in the exponent. Since the error exponent increases only with $\log$ SNR, the required number of sensors for -3 dB SNR is much larger than for 10 dB SNR for the same miss probability. It is clearly seen that P_M is still larger than 10^{-2} for 200 sensors whereas it is 10^{-4} with 20 sensors for 10 dB SNR case.

5. CONCLUSIONS

We have considered the detection of correlated signal using noisy sensors. We have derived the best error exponent for the Neyman-Pearson detector satisfying a fixed size constraint using the innovations and the spectral domain approaches. We have also investigated the properties of the error exponent. The error exponent is a function of SNR and correlation strength. The behavior of error exponent w.r.t. correlation strength is sharply divided to two regions depending on SNR. For SNR larger than unity the error exponent is monotone decreasing as correlation becomes strong. On the other hand it has a non-i.i.d. correlation strength that gives the maximum slope for SNR smaller than one. Using the property of error exponent, the optimal strategy for sensor scheduling has been derived.

The results presented in this paper have a generalization to the vector state-space model. Such a generalization is useful to consider more general scheduling schemes. In practice, the locations of sensors are random, and sensors may cease to function. Thus random sampling may need to be considered.
